AFOS-ERA VERIFICATION OF GUIDANCE AND
LOCAL AVIATION/PUBLIC WEATHER FORECASTS--NO. 9
(OCTOBER 1987-MARCH 1988)

Valery J. Dagostaro, Gary M. Carter, and J. Paul Dallavalle

1. INTRODUCTION

This is the ninth in a series of Techniques Development Laboratory (TDL) office notes which compare the performance of TDL's automated guidance with National Weather Service (NWS) local forecasts made at Weather Service Forecast Offices (WSFO's). Verification statistics are presented for the cool season months of October 1987 through March 1988 for probability of precipitation (PoP), precipitation type, snow amount, surface wind, cloud amount, ceiling height, visibility, and maximum/minimum (max/min) temperature. Verification summaries are provided for both forecast cycles, 0000 and 1200 GMT. The scores are those recommended in the NWS National Verification Plan (National Weather Service, 1982a).

Due to a change in the issuance time of the NWS official terminal forecasts (FT's), the local and guidance forecasts for the aviation weather elements (ceiling height, visibility, and wind speed and direction) no longer match. Moreover, the observations saved locally now correspond only to the valid time of the local forecasts. The issuance time of the local forecasts is based on local time rather than the forecast cycle. Although the actual time varies with time zone and changes from standard to daylight time, for simplicity, we will refer to the FT issuance times as if they occur at the same time for all stations. We verified the local forecasts associated with the FT issuance times of approximately 0900 and 1800 GMT. Persistence forecasts corresponding to the local forecasts are also now based on the local time. Since the valid time of the automated guidance has not changed, it is no longer possible to perform a comparative verification for the aviation weather elements.

For the aviation elements, the local forecasts, along with their corresponding persistence and verifying observations were collected locally at the WSFO's, transmitted via the Automation of Field Operations and Services (AFOS) system to the National Meteorological Center, and archived centrally by TDL. The automated guidance for these elements was also collected locally and transmitted to NMC. The persistence and verifying observations corresponding to the guidance were taken from hourly reports archived centrally by TDL. For the remaining weather elements, including the 42-h significant wind, all of the forecasts (both local and guidance) and the verifying observations were collected locally at the WSFO's and transmitted to NMC. The local collection system is described by Ruth and Alex (1987). The national AFOS-era verification data processing system is described in detail by Dagostaro (1985), while guidelines for the public/aviation forecast verification program are given in National Weather Service (1983).

The local PoP and max/min forecasts used for verification were official public weather forecasts obtained from the Coded City Forecast (FPUS4) bulletin. The local forecasts for the aviation weather elements were obtained from the FT's. In contrast, the local cloud amount, precipitation type, snow

amount, and 42-h significant wind forecasts were manually entered by the forecasters at the WSFO's. These subjective forecasts may or may not be based on the objective guidance. Also, surface observations as late as 2 hours before the first valid forecast time may have been used in preparation of the local forecasts.

The automated guidance was based on forecast equations developed through application of the Model Output Statistics (MOS) technique (Glahn and Lowry, 1972). In particular, these prediction equations were derived by using archived surface observations and forecast fields from the Limited-area Fine Mesh (LFM) model (Gerrity, 1977; Newell and Deaven, 1981). The surface observations used as predictors in these equations were taken at least 9 hours before the first verification valid time.

As noted in the sections which follow for each of the various weather elements, implementation of the AFOS-era verification system has introduced significant changes from past verifications in regard to the characteristics of the local forecasts and the verifying observations. For example, the local and guidance max/min temperature forecasts are verified by using max/min temperatures observed during approximately 12-h periods instead of 24-h (calendar day) periods. Also, the cloud amount observations are given in terms of total sky cover rather than opaque sky cover. Hence, we do not think it is meaningful to compare results for the 1987-88 cool season with statistics based on the pre-AFOS verification system (e.g., Carter et al., 1983).

In addition, due to the change in the issuance time of the FT's, direct comparison of the local statistics with those for the guidance is no longer possible for the aviation weather elements. Direct comparison of results for the local aviation elements for the 1987-88 cool season with statistics for previous cool seasons is also no longer possible.

2. PROBABILITY OF PRECIPITATION

MOS PoP forecasts were produced by the cool season prediction equations described in Technical Procedures Bulletin No. 289 (National Weather Service, 1980). This guidance was available for the first, second, and third periods, which correspond to 12-24, 24-36, and 36-48 hours, respectively, after 0000 and 1200 GMT. The predictors for the equation development were forecast fields from the LFM model and weather elements observed at the forecast site at 0300 or 1500 GMT. However, in day-to-day operations, surface observations at 0200 or 1400 GMT (or even 0100 or 1300 GMT) were used as input to the prediction equations nearly all the time. The LFM model schedule makes this possible, and the guidance is available earlier than if the 0300 and 1500 GMT observations were used.

The forecasts were verified by computing Brier scores (Brier, 1950) for 93 of the 94 stations listed in Table 2.1. Note that we used the standard NWS Brier score for PoP which is one-half the original score defined by Brier. Brier scores vary from one station to the next and from one year to the next because of changes in the relative frequency of precipitation. Therefore, we also computed the percent improvement over climate, that is, the percent improvement of Brier scores obtained from the local or guidance forecasts over analogous Brier scores produced by climatic forecasts. Climatic forecasts are defined as relative frequencies of precipitation by month and by station determined from a

15-yr sample (Jorgensen, 1967). Because local forecasters should be encouraged to depart from the guidance if they think it is incorrect, the number of times local forecasters deviated from the guidance by at least 20% were tabulated and the Brier score when such deviations occurred was computed.

Tables 2.2 and 2.7 present the 1987-88 cool season results for all 93 stations combined for the 0000 and 1200 GMT cycle forecasts, respectively. Tables 2.3-2.6 and Tables 2.8-2.11 show scores for the NWS Eastern, Southern, Central, and Western Regions, for the 0000 and 1200 GMT cycles, respectively.

3. PRECIPITATION TYPE

The objective conditional probability of precipitation type (PoPT) forecast system described in Technical Procedures Bulletin No. 319 (National Weather Service, 1982c) and Bocchieri and Maglaras (1983) provides categorical forecasts for three categories: freezing (freezing rain or drizzle), frozen (snow or ice pellets), and liquid (rain or drizzle). Precipitation in the form of mixed snow and ice pellets is included in the frozen category; any mixed precipitation type which includes freezing rain or drizzle is included in the freezing category; all other mixed precipitation types are included in the liquid category. In this report, the freezing, frozen, and liquid categories will be referred to as freezing rain, snow, and rain, respectively.

For verification purposes, local categorical forecasts of precipitation type are given for the 18-, 30-, and 42-h projections from 0000 and 1200 GMT. Note that this is a conditional forecast, that is, it's a forecast of the type of precipitation if precipitation actually occurs. Therefore, a precipitation type forecast is always recorded. Similarly, the PoPT guidance is available whether or not precipitation occurs.

Table 3.1 lists the 86 stations used for the precipitation type verification. The verification sample included only those cases in which precipitation actually occurred within ± 1 hour of the forecast valid time. If a combination of precipitation types occurred during the 2-h period, the verifying observation was considered as freezing if freezing precipitation was observed at any time, or frozen if frozen (but not freezing) precipitation occurred. Note that an observation of mixed frozen and liquid precipitation types was included in the frozen category, while the guidance forecasted the liquid category if mixed frozen and liquid precipitation was expected. Also, since we were concerned that some forecasters may not have put much effort into making the conditional forecasts when they considered precipitation to be unlikely, we used cases only when the local PoP was $>30\%$. The PoP forecasts were valid for 12-h periods centered on the 18-, 30-, and 42-h projections from both 0000 and 1200 GMT.

Based on the three precipitation type categories, forecast-observed contingency tables were constructed. Bias by category,¹ probability of detection

¹ In the discussion of precipitation type, snow amount, surface wind, cloud amount, ceiling height, and visibility, bias by category refers to the number of forecasts of a particular category (event) divided by the number of observations of that category. A value of 1.0 denotes unbiased forecasts for a particular category.

(POD),² false alarm ratio (FAR),³ skill score,⁴ and percent correct were calculated from contingency tables of precipitation type. Tables 3.2 and 3.3 show the verification results for 0000 and 1200 GMT, respectively. The number of freezing rain cases is small, and conclusions for that category must be made with caution.

4. SNOW AMOUNT

The objective probability of snow amount forecast system described in Technical Procedures Bulletin No. 318 (National Weather Service, 1982b) and by Bocchieri (1983) provides categorical forecasts for four categories of snow amount: <2, 2 or 3, 4 or 5, and ≥ 6 inches. In particular, prediction equations based on LFM model forecasts are used to produce conditional probabilities of snow amount for the three categories of ≥ 2 , ≥ 4 , and ≥ 6 inches. These conditional probabilities are converted to unconditional probability forecasts through the use of the MOS PoP and PoPT forecasts. The unconditional probability forecasts are converted to categorical forecasts through the use of the threshold technique described in Technical Procedures Bulletin No. 318.

Verification scores were computed for both local and guidance forecasts for 82 of the 86 stations listed in Table 3.1. The local and guidance forecasts were verified for the 12-24 h period from both 0000 and 1200 GMT, since the guidance was provided only for this projection.

We constructed forecast-observed contingency tables for four categories of snow amount. These tables were used for computing several different scores: bias by category, percent correct, skill score, threat score,⁵ POD, and FAR. The percent correct and skill score were calculated from all four categories. The bias by category, threat score, POD and FAR were calculated separately for the three cumulative categories of ≥ 2 , ≥ 4 , and ≥ 6 inches. Table 4.1 shows comparative verification scores for the snow amount forecasts for both cycles.

5. SURFACE WIND

The objective surface wind forecasts were generated by the cool season, LFM-based equations described in Technical Procedures Bulletin No. 347 (National Weather Service, 1984). Prior to the 1983-84 cool season, the surface wind prediction equations were rederived to account for the latest available LFM data. The objective surface wind forecast is defined in the same way as the

²The POD is the ratio of the number of times a particular category was correctly forecast to the total number of observations of that category.

³The FAR is the ratio of the number of times a particular category was incorrectly forecast to the total number of forecasts of that category.

⁴The skill score used throughout this report is the Heidke skill score (Panofsky and Brier, 1965).

⁵Threat score = $H/(F+O-H)$, where H is the number of correct forecasts of a category, and F and O are the number of forecasts and observations of that category, respectively.

observed wind, namely, the 1-min average wind direction and speed for a specific time. All objective forecasts of wind speed were adjusted by an "inflation" technique (Klein et al., 1959) involving the multiple correlation coefficient and the mean value of wind speed for each station and forecast valid time.

We verified both the local and guidance forecasts for three projections; however, due to the change in issuance time of the FT's, the projections no longer match. The guidance forecasts are valid at 12-, 18-, and 24-h projections from both the 0000 and 1200 GMT cycles, while the local forecasts correspond to approximately 3-, 9-, and 15-h projections from the FT issuance times of approximately 0900 and 1800 GMT.

Although the MOS and local forecasts were verified separately, we used the same method of verification as in previous seasons. First, for those cases in which the wind speed forecasts were >10 kt, the mean absolute error and the mean algebraic error (forecast minus observed wind speed) of the forecasts were computed. Cases where the observed wind was calm were then eliminated from this sample and the MAE of direction was computed. Second, for all cases where the forecasts were available, the skill score, percent correct, bias by category, and threat score were computed from contingency tables of wind speed. The definitions of the categories used in the contingency tables for wind speed and direction are given in Table 5.1. The threat score used here was calculated by combining events of the upper two categories (winds >28 kt). In addition, for all cases in which the wind speed forecasts were at least 10 kt, the skill score for the wind direction forecasts was computed from contingency tables. The 92 stations used in the verification are listed in Table 2.1.

For the guidance forecasts, the results for all 92 stations combined for the 0000 and 1200 GMT cycles are presented in Tables 5.2 and 5.7, respectively. Tables 5.3-5.6 and 5.8-5.11 show guidance scores for the NWS Eastern, Southern, Central, and Western Regions for 0000 and 1200 GMT, respectively. For the local forecasts, Table 5.12 (5.17) shows the results for all 91 (92) stations combined for the FT issuance time of approximately 0900 (1800) GMT. Similar local forecast results for the NWS Eastern, Southern, Central, and Western Regions are presented in Tables 5.13-5.16 and 5.18-5.21, respectively, for the two issuance times.

In addition, 42-h forecasts of winds >23 kt were collected as part of the AFOS-era verification system. Note that the change in FT issuance time did not affect these forecasts; hence, a comparative verification of the local and guidance forecasts was possible. Both the local and guidance forecasts correspond to the 42-h projection from both the 0000 and 1200 GMT cycles. Since these forecasts specify the occurrence (or non-occurrence) of an operationally significant wind, they were verified against the highest observed sustained wind within ± 3 hours surrounding the forecast valid time. For purposes of comparison, and analogous to the development of the MOS prediction equations, another set of scores was calculated by using the 1-min average wind observed at the exact forecast valid time. The results for all 92 stations combined are given in Tables 5.22 and 5.23 for the 0000 and 1200 GMT cycles, respectively.

6. CLOUD AMOUNT

Prior to February 24, 1988, the objective cloud amount forecasts were produced by the prediction equations described in Technical Procedures Bulletin No. 303 (National Weather Service, 1981). For the remainder of the cool season, the forecasts were produced by the prediction equations described in Technical Procedures Bulletin No. 378 (National Weather Service, 1988). In both cases, the forecast equations used LFM model output and either 0100 or 0200 (1300 or 1400) GMT surface observations to produce probability forecasts of the four categories of cloud amount shown in Table 6.1. We converted the probability estimates to "best category" forecasts by an algorithm that produced good bias characteristics (bias of approximately 1.0 for each category) on the developmental sample. The algorithm used to obtain the best category for the new prediction equations is described in Technical Procedures Bulletin No. 378.

We compared the local forecasts with a matched sample of guidance forecasts for the 94 stations listed in Table 2.1 for the 12-, 18-, and 24-h projections from 0000 and 1200 GMT. The surface observations used for verification were converted to the cloud amount categories given in Table 6.1. Four-category (clear, scattered, broken, and overcast), forecast-observed contingency tables were prepared from the local and objective categorical predictions. Using these tables, we computed the percent correct, skill score, and bias by category. Prior to the 1983-84 cool season, opaque sky cover amounts from surface observations were used in determining the observed categories. However, the hourly surface reports from which the verifying observations are now taken do not record total opaque sky cover as part of the observation; hence, thin clouds are also included. For example, a report of overcast with eight tenths opaque and two tenths thin, which previously was put into the broken category, now is categorized as overcast. The result of this change is to decrease (increase) the number of observations of the broken (overcast) category compared to previous verifications. This change has greatly affected the overall bias by category statistics for both the guidance and local forecasts.

The results for all stations combined are shown in Tables 6.2 and 6.7 for the 0000 and 1200 GMT cycle forecasts, respectively. Tables 6.3-6.6 and Tables 6.8-6.11 show scores for the NWS Eastern, Southern, Central, and Western Regions, for the 0000 and 1200 GMT cycles, respectively.

7. CEILING AND VISIBILITY

During the 1987-88 cool season, the ceiling and visibility guidance was produced by the prediction equations described in Technical Procedures Bulletin No. 303 (National Weather Service, 1981). Operationally, the guidance was based primarily on LFM model output and either 0100 or 0200 (1300 or 1400) GMT surface observations.

Verification scores were computed separately for the local and guidance forecasts. A comparative verification of local and persistence forecasts was performed for 91 (92) of the 94 stations listed in Table 2.1 for the FT issuance time of approximately 0900 (1800) GMT. The local forecasts and verifying observations correspond to approximately 3-, 6-, 9-, and 15-h projections from the beginning of the scheduled FT valid period. Persistence is also based on the local time, and the projections are from the beginning of the scheduled FT valid period.

A comparative verification of guidance and persistence forecasts was performed for the same 91 (92) stations for the 0000 (1200) GMT cycle. Here, persistence for the 0000 (1200) GMT forecast cycle was based on an observation taken at the subsequent 0900 (2100) GMT. The objective and persistence forecasts were verified for the 12-, 18-, and 24-h projections from both cycles. Note that the persistence forecasts for the 12-, 18-, and 24-h projections are actually 3-, 9-, and 15-h forecasts, respectively, from the latest available surface observation, and in this sense, the guidance forecasts are usually 10-, 16-, and 22-h forecasts.

We constructed forecast-observed contingency tables for the four categories of ceiling and visibility given in Table 7.1. These categories were used for computing several different scores: bias by category, percent correct, skill score, and log score.⁶ Table 7.2 (7.3) shows the MOS ceiling height verification results for all 91 (92) stations combined for the 0000 (1200) GMT cycle. Table 7.4 (7.5) presents the local ceiling height scores for the same 91 (92) stations except for the FT issuance time of approximately 0900 (1800) GMT. Visibility scores are given for all stations combined for the MOS forecasts in Tables 7.6 and 7.7 for the 0000 and 1200 GMT cycles, respectively. Similarly, results for the local forecasts are given in Tables 7.8 and 7.9 for the FT issuance times of approximately 0900 and 1800 GMT, respectively.

8. MAXIMUM/MINIMUM TEMPERATURE

Throughout the 1987-88 cool season, the max/min temperature guidance was generated by the prediction equations described in Technical Procedures Bulletin No. 356 (National Weather Service, 1985b). These equations forecast daytime max and nighttime min temperatures. During the cool season, daytime is defined as 9 a.m. to 7 p.m. Local Standard Time (LST), while nighttime extends from 7 p.m. to 9 a.m. LST. The guidance equations were developed by stratifying archived LFM model forecasts, station observations, and the first two harmonics of the day of the year into seasons of 3-mo duration (Erickson and Dallavalle, 1986). The fall season is defined as September-November; the winter, as December-February; and the spring, as March-May. During the 0000 GMT cycle, the MOS max/min guidance is valid for periods corresponding to today's max, tonight's min, tomorrow's max, and tomorrow night's min. Similarly, for the 1200 GMT forecast cycle, guidance is produced for tonight's min, tomorrow's max, tomorrow night's min, and the day after tomorrow's max. Station observations at 0000 GMT (1200 GMT) are used as possible predictors only in the first period forecast of today's max (tonight's min). The valid periods of the guidance closely approximate those of the local forecaster who makes predictions of today's high, tonight's low, and so forth.

In this publication, we present results for both guidance and local forecasts that were verified by using observations approximating the daytime high or nighttime low. For the local AFOS-era verification software (Ruth and Alex, 1987), daytime is defined as 7 a.m. to 7 p.m. LST and nighttime as 7 p.m. to 8 a.m. LST. The local program scans the synoptic and hourly reports to determine if the max/min observation adequately represents the daytime or nighttime

⁶The log score is proportional to the absolute value of $\log_{10} f_i - \log_{10} o_i$, where f_i is the forecast category for each case and o_i is the observed category for each case. The result is averaged over all cases and scaled by multiplying by 50.

period. If this observation is satisfactory, it is kept. If, however, the reported value is not representative of the day or night period, then an algorithm is used to deduce an appropriate value from available synoptic and hourly temperature observations. The local forecaster is also provided the option of replacing the estimated observation with the exact nighttime low or daytime high. It's important to note, then, that the verification observations used in this report correspond reasonably well to the local and guidance forecast periods.

We verified the local and MOS max/min temperature forecasts for both the 0000 and 1200 GMT cycles. The mean algebraic error (forecast minus observed temperature), mean absolute error, percent of absolute errors $>10^{\circ}\text{F}$, probability of detection⁷ of min temperatures $\leq 32^{\circ}\text{F}$, and false alarm ratio⁸ for min temperatures $\leq 32^{\circ}\text{F}$ were computed for 93 stations in the conterminous United States (see Table 2.1). At 0000 (1200) GMT, the local and guidance max temperature forecasts are valid for daytime periods ending approximately 24 (36) and 48 (60) hours after 0000 (1200) GMT. Similarly, at 0000 (1200) GMT, the local and guidance min temperature forecasts are valid for nighttime periods ending about 36 (24) and 60 (48) hours after 0000 (1200) GMT. Note that the local forecasters occasionally may not have put much effort into making the 60-h min forecasts from 0000 GMT, especially during severe weather events.

For all stations combined, the results for 0000 and 1200 GMT are shown in Tables 8.1 and 8.6, respectively. Similarly, Tables 8.2-8.5 give the 0000 GMT verification scores for the Eastern, Southern, Central, and Western Regions, respectively. Tables 8.7-8.10 show scores by NWS region for the 1200 GMT cycle.

9. SUMMARY

Highlights of the 1987-88 cool season verification results, summarized by general type of weather element, are:

- o Probability of Precipitation - The PoP verification involved 93 stations and forecast projections of 12-24, 24-36, and 36-48 hours from 0000 and 1200 GMT. The NWS Brier scores for all stations and both forecast cycles combined show that the local forecasts were 9.4% better than the guidance for the first period, 7.3% better for the second period, and 7.1% better for the third period. These overall average improvements over guidance are better than those for the previous cool season (Dagostaro et al., 1987). Depending on the projection and cycle, the local forecasters deviated by 20% or more from the guidance about 13% of the time. For these cases, the NWS Brier scores for all stations and both forecast cycles combined indicate that the local forecasts were 22.8% better than the guidance for the first period, 19.0% better for the second period, and 17.8% better for the third period. Finally, the percent improvement over

⁷Here, the probability of detection is defined to be the fraction of time the min temperature was correctly forecast to be $\leq 32^{\circ}\text{F}$ when the previous day's min was $\geq 40^{\circ}\text{F}$.

⁸Here, the false alarm ratio is defined to be the fraction of forecasts of $\leq 32^{\circ}\text{F}$ that failed to verify when the previous day's min was $\geq 40^{\circ}\text{F}$.

climate scores for all three periods and both forecast cycles indicate that the local and guidance scores were worse than those for the previous cool season.

- o Precipitation Type - Local and guidance forecasts for 86 stations and projections of 18, 30, and 42 hours from 0000 and 1200 GMT comprised the comparative verification. Only those cases for which the local PoP was $\geq 30\%$ were verified, and surface observations within ± 1 hour of the forecast valid time were used. Based on three-category (freezing rain, snow, rain) contingency tables, the scores for all stations combined for all three projections and both cycles indicate that the local and guidance forecasts performed at about the same level of accuracy. Overall, the scores for all three categories were generally about the same as those for the previous cool season, except for the POD and FAR for the snow category. Both of these scores show an improvement in local and MOS forecasts of frozen precipitation over those for the previous cool season in conjunction with an increase in the number of events for this category.
- o Snow Amount - The snow amount verification involved 82 stations for the 12-24 h period from 0000 and 1200 GMT. In terms of skill score, threat score, POD, and FAR, the local forecasts were generally as good as or better than the guidance for all three categories for both cycles. In terms of bias by category, neither the local forecasts nor the guidance was clearly better. The scores for both the local forecasts and the guidance were generally worse than those for the previous cool season for the ≥ 4 and ≥ 6 inch categories.
- o Surface Wind - Statistics were computed for local and guidance forecasts of surface wind speed and direction. Local forecasts for 91 (92) stations for projections of around 3, 9, and 15 hours from the FT issuance times of approximately 0900 and 1800 GMT were verified. These results are not directly comparable to those for previous seasons. Guidance forecasts for the same 91 (92) stations for projections of 12, 18, and 24 hours from 0000 and 1200 GMT were verified. The results for the guidance are similar to those for the previous cool season. During the past four cool seasons, the MOS guidance underforecast the number of winds > 18 kt. This appears to be directly related to the change in the LFM's surface stress profile which was implemented in January 1985 (National Weather Service, 1985a).

The 42-h significant wind verification involved the comparison of local and guidance forecasts of winds > 23 kt for 92 stations for the 42-h projection from 0000 and 1200 GMT. In terms of bias by category, the guidance was considerably better than the local forecasts when the verifying observation was the 1-min average. The bias of the local forecasts was still high, but much less so, when the verifying observation was the ± 3 -h maximum speed. The accuracy and skill measures reflect the respective biases of the MOS and local forecasts. For a rare event such as this, underforecasting the event (bias < 1.0) usually leads to a higher percent correct with lower skill and threat scores.

- o Cloud Amount - The verification for cloud amount involved the comparison of local and guidance forecasts for 94 stations for projections of 12, 18, and 24 hours from 0000 and 1200 GMT. The skill scores and percent correct for all stations combined indicate both the 0000 and 1200 GMT cycle local forecasts were better than the corresponding guidance for the 12-h projection, while the guidance was better than the local forecasts for the 18- and 24-h projections. In terms of bias by category, the guidance was better than the local forecasts for the clear, scattered, and broken categories. The local forecasts were generally better than the guidance for the overcast category. Overall, the results were similar to those for the previous cool season, except that the tendency for both the guidance and local forecasters to overforecast the scattered category appears to have increased.
- o Ceiling and Visibility - Both the local and guidance forecasts were verified against their corresponding persistence forecasts. For the local forecasts, a comparative verification was performed for the 91 (92) stations for projections of around 3, 6, 9, and 15 hours from the FT issuance times of approximately 0900 and 1800 GMT. For both forecast cycles combined, the log scores, percent correct, and skill scores for both ceiling and visibility show that persistence was generally as good as or better than the locals for the 3-h projection, while the locals were better for the 6-, 9-, and 15-h projections. In terms of bias by category, the locals almost always underforecast the ceiling height \leq 900 ft and the visibility \leq 2 3/4 mi. These results are not directly comparable to those for previous seasons.

For the guidance, the verification involved the comparison of MOS forecasts and persistence for the same 91 (92) stations for projections of 12, 18, and 24 hours from 0000 (1200) GMT. These are actually 3-, 9-, and 15-h forecasts from the latest available surface observations for persistence, and in this sense, they are usually 10-, 16-, and 22-h forecasts for the guidance. For both forecast cycles combined, the log scores, percent correct, and skill scores for ceiling show that persistence was better than the guidance for the 12-h projection, while the guidance was generally better for the 18- and 24-h projections. The bias by category results varied from projection to projection and cycle to cycle. For visibility, the log score, percent correct, and skill score for both cycles combined show that persistence was clearly better than the guidance for the 12-h projection. In terms of bias by category, the guidance was generally as good as or better than persistence for all cycles and projections. In terms of log score and percent correct, the results for ceiling and visibility were better than those for the 1986-87 cool season, but worse in terms of skill score.

- o Maximum/Minimum Temperature - Objective and local forecasts were verified for 93 stations for both the 0000 and 1200 GMT cycles. At 0000 (1200) GMT, the local maximum temperature forecasts were valid for daytime periods ending approximately 24 (36) and 48 (60) hours after 0000 or 1200 GMT, while the minimum temperature forecasts were valid for nighttime periods ending approximately 36 (24) and 60 (48) hours after initial model time. The valid periods of the

guidance closely approximate those of the local forecasts. As verifying observations, max or min temperatures for daytime or nighttime intervals were used.

For all stations and projections combined, we found the mean absolute errors of the local max and min temperature forecasts were 0.3°F and 0.2°F, respectively, more accurate than those for the MOS guidance. In every region and for all projections, the local forecasters were able to improve over the MOS guidance, both in terms of mean absolute error and the percentage of errors >10°F. Compared to the 1986-87 cool season verifications, the MOS guidance was 0.2°F worse in terms of mean absolute error for all stations and projections combined, while the local forecasts were 0.1°F worse overall than those for the previous cool season.

10. ACKNOWLEDGMENTS

We are grateful to Eston Pennington for archiving the data, and to Karen Yip for typing the text.

Table 2.1. Ninety-four stations used for comparative verification of MOS guidance and local probability of precipitation, surface wind, cloud amount, ceiling height, visibility, and max/min temperature forecasts. Please note that LAX was not included in the PoP and max/min temperature verifications, and LBB and ELP were not included in the surface wind, ceiling height, and visibility verifications. TCC was not available during the 0000 GMT cycle for the local surface wind, ceiling height, and visibility.
